Kwame Nkrumah University of Science and Technology, Ghana

ABSTRACT

To maximize the benefits of LTE cellular networks, careful and proper planning is needed. This requires the use of accurate propagation models to quantify the path loss required for base station deployment. Deployed LTE networks in Ghana can barely meet the desired 100Mbps throughput leading to customer dissatisfaction. Network operators rely on transmission planning tools designed for generalized environments that come with already embedded propagation models suited to other environments. A challenge therefore to Ghanaian transmission network planners will be choosing an accurate and precise propagation model that best suits the Ghanaian environment. Given this, extensive LTE path loss measurements at 800MHz and 2600MHz were taken in selected urban and suburban environments in Ghana and compared with 6 commonly used propagation models. Improved versions of the Ericson, SUI, and ECC-33 developed in this study predict more precisely the path loss in Ghanaian environments compared with commonly used propagation models.

KEYWORDS

Propagation Models, Path loss Exponent, Root Mean Square Error, Signal Reference Received Power(RSRP).

1. INTRODUCTION

Cisco’s visual networking index, 2017-2022 predicts that the IP traffic recorded annually around the globe is estimated at 4.8 Zb by 2022. This translates to a threefold increase over the next five years [1]. Mobile data subscription in Ghana as of July 2018 stood at twenty-nine million, one hundred and eighty-one thousand, eight hundred and sixty-three (29,181,863) [2]. For a country with an estimated total population of thirty million [3], it shows the high demand for data and broadband services.

With this growing demand for bandwidth in mobile communication as user numbers keep increasing significantly, mobile networks have evolved from 1G - 4G to meet the demand over the years. In Ghana, Blu telecom, Busy internet, Surfline, MTN, and recently Vodafone have commercially deployed 4G LTE networks for higher throughputs and improved user experience. However, this hasn’t been completely achieved since the expected throughput of 100Mbps is barely realized leading to dissatisfaction among customers. This has resulted in a lot of complaints and sanctioning from the National communications authority[4].

Transmitted signals from a base station suffer severe attenuation as they propagate through space leading to degradation in signal strength and quality[5]. This severe attenuation is introduced due to reflection, diffraction, and scattering of the signal as it impinges on obstacles. For subscribers of a network who have varying mobility, it is imperative to design a mobile network so that they have robust signal levels at all locations. To achieve this, Conditions for
radio propagation need to be well understood and predicted as accurately as possible. Propagation models are instrumental in wireless network planning as they support interference estimates, frequency assignments, and cell coverage assessment and other parameters[6].

Empirical propagation models that are mostly used are however environment specific and are developed based on a specific propagation environment of interest[7]. Any little deviation in characterizing the propagation environment under investigation affects the efficiency of propagation models designed from the area[8],[9]. Therefore, the use of propagation models in settings other than those intended to be used might lead to inaccurate prediction which affects system performance[10],[11]. To investigate these claims, the approach adopted in this project is to take Signal Reference Received Power (RSRP) values from deployed cell sites and compare with predictions from 4 propagation models at 800MHz and 6 models at 2600MHz. This approach will help us develop modified and improved versions of already existing propagation models suited for the Ghanaian environment.

The rest of the paper is organized as follows: Section 2 reviews some relevant work in this field. Section 3 presents the measurement procedure at investigated environments and empirical propagation models under consideration. Results are presented in Section 4 and Section 5 concludes the study.

2. RELATED WORKS

Considering the increased demand placed on mobile communication, higher throughputs and seamless connectivity, designing LTE networks in compliance with the performance metrics it promises is crucial. Numerous studies have gone into finding propagation models that predict accurately the path loss in the USA, Europe, Africa, and Asia to improve network performance for both voice and data communication.

How best current propagation models will perform when used in wireless environments other than those originally intended for frequently deviate from the ideal[6]. Numerous studies around the globe, however, show that many industry-standard path loss models perform effectively when adjusted to measured data from these areas[12],[13]. In[12], Path loss measured data at 3.5GHz in Cambridge was compared with the predictions of three empirical propagation models. Results indicated that the SUI and COST-231 models over-estimated path loss in this environment. The closest fit to the measurement data was the ECC-33 model. It was therefore recommended for use in urban environments.

The least-square method was used in [13] to optimize the Hata empirical path loss model for accurate prediction suited to a suburban area in Malaysia. Outdoor measurements were taken in Cyberjaya, Malaysia at a frequency range of 400MHz to 1800 MHz. Measurements were then compared with the existing models from which the Hata model showed the best fit. The optimized Hata model was used and validated in the Putrajaya region to detect the relative error to evaluate its efficiency. Smaller mean relative error was recorded hence showing that the optimization was done successfully.

Propagation models are presented in [14] for LTE Advanced Networks. Path loss for varying environments (rural, suburban and dense urban) were computed using the following propagation models, COST-231 Walfisch–Ikegami model, SUI, ECC-33, Okumura extended Model and COST-231 Hata Model using MATLAB. Three frequencies between 2.3GHz and 3.5 GHz were considered in this work. Results presented indicated the COST-231 Hata model agreed better, giving the least path loss in all the environments compared with the other models. This work, however, did not compare the prediction of empirical models with measured data but only based
on the model with the least path loss. The conclusion made favoring the cost 231 Hata model by simulation as agreeing best in all environments might be misleading.

Extensive measurements in [10] taken in Lagos at a frequency of 3.4GHz made a comparison with 6 standard propagation models. It was concluded that the COST 231-Hata and Ericson models showed the best performance in urban and suburban areas. Recent works in [16] also compared the efficiencies of empirical, heuristic, and geospatial methods used for signal path loss predictions using data collected in urban Nigerian cities to develop path loss models. The developed models and empirical models were compared with field measured data. All models gave acceptable RMSE values excluding the ECC-33 and Egli models. Empirical models were the simplest and most commonly applied of the three techniques submitted. Their work, therefore, emphasized the further improvement of empirical models for optimum prediction. A hybrid of heuristic and empirical models for prediction was recommended to decrease the errors associated with empirical models.

Works have also gone into comparing path loss of urban and suburban areas and to ascertain if a particular propagation model can be used for both settings. [17] showed that propagation models in urban areas experience higher losses compared with suburban areas. For all environments, no single model could be proposed.

On the background that deployed WiMAX networks, failed to meet the optimum service quality requirements for delivering continuous wireless connectivity requests in the sub-Saharan region needed for emerging mobile applications, [18] investigated the throughput performance of a deployed 4G LTE Site to ascertain if LTE meets the bandwidth demand needed for data-centric broadband applications. Field data from a deployed 4G LTE BS in Ghana operating at 2600 MHz recorded a maximum throughput of 29.9 Mbps per sector. A maximum throughput of 62.318 Mbps was recorded at the downlink for customers within 2.5 km of the cell range from the BS. It was concluded that 4G LTE can meet the ever-increasing demand of Ghanaians for broadband. This conclusion was made after comparing these throughputs with the desired throughput required to sustain data-centric broadband applications.

Works in the Ghanaian environment focusing on WiMAX networks in the 2500-2530 MHz band was presented in [11]. The measurement from a deployed WiMAX site around the university of Ghana, Accra was compared with the prediction of four empirical models. The extended COST-231 model was selected as the model that best fits the measured data because it recorded the least RMSE and a higher correlation coefficient. This model was recommended therefore for efficient radio network planning in Ghana and the sub-region at large. It was also concluded that no particular propagation model can be used to forecast coherent outcomes for all propagation settings. The reason for this was the variations in weather and geography. Recommendations were made to consider varying terrain parameters.

Intensive measurements in separate environments must be conducted to parameterize a model. The parameters of the channel model are then adjusted to suit the measurement outcomes [19]. It is imperative therefore from the works reviewed to evaluate the performance of industry-standard propagation models proposed for 4G LTE networks by considering different Ghanaian environments. With several path loss models performing differently in different environments, it is, therefore, essential to determine which of the most frequently used models is best suited for 4G LTE networks in Ghana. Further improving the suited model for more accurate prediction pertinent to the Ghanaian and Sub-Saharan environment will facilitate effective deployment of LTE networks by operators, meeting the promises the Standard came with. This, in the end, will afford subscribers the chance to enjoy seamless connectivity leading to customer satisfaction and loyalty.
3. Measurements

3.1. Procedure

Received signal reference power (RSRP) values in dBm were taken at 10 Base stations in seven selected areas in Ghana with varying environmental conditions. A drive test was conducted using phones connected via the USB port to a computer with LTE software (Genex probe) installed on it. Genex probe serves as a data collection software interface. A GPS was attached for location finding and tracking distance covered. The frequency was set to 800MHz for the first test case at five base stations and 2600MHz for the second test case for the other five base stations. At the various sectors of each LTE site in these environments, RSRP values at a varying distance starting from a reference distance \((d_0)\) of 50m to 500m with 50m intervals were recorded. The Transmit - Receiver distance was limited to 500m to reduce the impact of interference from neighboring cells and also to cater for obstructions in the way of the drive. A receiver antenna height of 1.5m was maintained throughout the measurement campaign. Measured data is sent via the phones to the computing device which stores the data as recorded log files. These recorded log files are then interpreted and analyzed. Field measurements were taken between February and May. The RSRP in dBm was taken along the LOS and NLOS of the fixed base stations with heights ranging between 16m and 35m. The laptop having GENEX software installed on it, the phone and the GPS were set up in the drive test vehicle as shown in figure 1.

![Figure 1 Measurement set up](image_url)

3.2. Description of Environments

Drive test measurements were taken in the following environments in Ghana.

1. **Adum**: This is an urban area located in the central hub of Kumasi, in the Ashanti Region of Ghana with coordinates 6.6919°N,1.6287°W. It is highly populated and characterized by a lot of business activity. Present in Adum are a lot of high-rise buildings.

2. **Techiman**: This is an urban area that serves as the capital of the newly created Bono East Region of Ghana with coordinates 7.5909° N, 1.9344° W. It is characterized by quite many high-rise buildings and a lot of farming and business activities.

3. **Agogo**: This is a suburban area in the Asante Akyim North Municipal District of the Ashanti Region of Ghana with coordinates 6.7991° N, 1.0850° W. Agogo is approximately 80 kilometers east of Kumasi, with moderate population and buildings. Buildings are mostly not high rise and are a little isolated from each other. The terrain is relatively flat.

4. **Afrancho**: It is a populated suburban community in the Bosomtwe District of the Ashanti region of Ghana with coordinates 6° 33' 0" N, 1° 38' 0" W. it is characterized by relatively hilly terrain with the presence of valleys.
5. New Dorma: suburban area in the Brong Region of Ghana. It is Characterised by a mixture of flat and hilly terrains covered with a lot of vegetation. It lies on coordinates 7° 16' 39" N, 2° 52' 42" W.

6. Berekum: This is a Municipal located in the Bono Region of Ghana. It lies on coordinates 7° 27' N, 2° 35' W.

7. Sunyani: This is an Urban populated city serving as the capital of the Bono Region of Ghana. Sunyani is surrounded by the forested Southern Ashanti uplands. It lies on coordinates 7° 20' N, 2° 20' W.

8. **Modeling Parameters**

Parameters used in generating the path loss for the different propagation models are given in Table 1.

### 3.3. Propagation Models

The following propagation models were considered in this work.

I. Free Space Path Loss Model

II. Hata Model

III. COST- 231 Model

IV. ECC-33 Model

V. Stanford University Interim (SUI) Model

VI. Ericson Model

### 3.3.1. Free Space Path Loss

The equation given by Friis is used to estimate the power reaching a receiving antenna separated from the transmitting antenna by a distance in free space. This model relates the path loss to frequency and distance with the assumption of an unobstructed line of sight between the transmitter and receiver. Path loss by this model is as given in equation (1)

\[ P_l = 32.44 + 20\log(d) + 20\log(f) \]

\[ f = \text{frequency in MHz} \]

\[ d = \text{distance in Km} \]
3.3.2. HATA Model

The Hata-Okumura model stands as the most important and popular empirical model. Curves presented by Yoshihisa Okumura [30] for path loss estimation were tedious to estimate. The Hata-Okumura model converts these curves into mathematical equations for path loss estimation[20]. The Hata model provides equations based on extrapolations to Okumura's curve measurements[20]. As a definitive formula, Hata provided the loss of urban spread as well as extra correction factors for suburban, and rural areas. The model is applicable for frequencies ranging from 150 MHz to 1500 MHz. Path loss for the Hata model as given in [5] and [21] is given in (2).

\[ PL_{\text{urban}}(dB) = 69.55 + 26.16 \log(f) + 13.82 \log(h_t) + h_r + [44.9 + 6.55 \log(h_t)] \log(d) \] (2)

for suburban areas path loss is computed as in (3)

\[ PL_{\text{suburban}}(db) = PL_{\text{urban}} - 2[\log(f)]^2 - 5.4 \] (3)

\[ f = \text{frequency in MHz}, \quad d = \text{distance in Km}, \quad h_r = \text{mobile antenna height in meters} \quad \text{and} \quad h_t = \text{base station antenna height in meters} \]

In small and medium cities,

\[ h_r = (1.1 \log(f) - 0.7) h_r + (1.56 \log(f) - 0.8) \] (4)

For large cities,

\[ h_r = 3.2[\log(11.75 h_r)]^2 - 4.97 \text{ for } f > 300MHz \] (5)

\[ \alpha h_r = 8.29 \left[ \log(1.54 h_r) \right]^2 - 1.1 \text{ for } f \leq 300MHz \] (5)

3.3.3. COST-231 Model

The COST-231 model was implemented by the European Co-operative for Scientific and Technical Research (COST), which was an expansion of the Hata-Okumura Model for working frequency 1500 - 2000 MHz. This propagation model is obtained from the Hata model and relies on parameters such as frequency, antenna height, distance and base station height for path loss estimation. It can be applied for suburban and urban environments and as such, it is an outdoor propagation model.

The path loss equation for this mode expressed in dB as given in [24] is shown below

\[ PL(dB) = 46.3 + 33.9 \log(f) - 13.82 \log(h_{re}) - a(h_a) + (44.9 - 6.55 \log(h_{re})) \log(d) + C_m \] (6)

where \( f \) is the frequency specified in MHz, \( d \) is the distance between the base station and mobile antennas given in km, \( h_{re} \) is the base station antenna height above ground level in meters, \( h_{re} \) is the mobile antenna height in meters, \( C_m \) is defined as 0 dB for suburban or open environments and 3 dB for urban environments.

\( a(h_a) \) is defined for large areas as

\[ a(h_a) \text{ dB} = 8.29 \left( \log \left( 1.54 h_{re} \right) \right)^2 - 1.1 \text{ for } f \leq 300MHz \] (7)

\[ a(h_a) \text{ dB} = 3.2 \left( \log \left( 11.75 h_{re} \right) \right)^2 - 4.97 \text{ for } f > 300MHz \] (8)

\[ h_{re} \text{ is defined as 0 dB for suburban or open environments and 3 dB for urban environments.} \]
In medium or small cities,

\[(h_d dB = (1.1\log(f) - 0.7)h_t + (1.56\log(f) - 0.8))\]

(9)

### 3.3.4. ECC-33 Path Loss Model

Measurement data for Okumura’s propagation model was gathered in Tokyo, Japan. Urban cities in Tokyo were segmented into categories of large and medium city and Correction factors made available for suburban and open environments. Tokyo which is a highly built-up area has characteristics very much different from typical European suburban areas. This was the reason behind the Electronic communication Committee (ECC) extrapolating the original Okumura measurement data and modifying its postulations so it closely fits wireless systems in Europe. This resulted in the ECC-33 model. The path loss equation for this model is given in [15]

\[
PL = A_{fs} + A_{bm} - G_b - G_r
\]

(10)

Where \( A_{fs} \) is the free space path loss, \( A_{bm} \) is the basic median path loss \( G_b \), is the transmitter antenna height gain factor and \( G_r \) is the receiver antenna height gain factor.

Each of these parameters is expressed fully as:

\[
A_{fs} = 92.4 + 20\log_{10}(d) + 20\log_{10}(f)
\]

(11)

\[
A_{bm} = 20.41 + 9.83\log_{10}(d) + 1.794\log_{10}(f) + 9.56\log_{10}(f)^2
\]

(12)

\[
G_b = \log_{10}(\frac{hb}{200}) \left[ 13.958 + 5.8\log_{10}(d) \right]
\]

(13)

When considering medium city environments

\[
G_r = \left[ 42.57 + 13.7\log_{10}(f) \right] \left[ \log_{10}(hr) - 0.585 \right]
\]

(14)

For large cities,

\[
G_r = 0.759hr - 1.862
\]

(15)

where \( f \) is frequency expressed in \( GHz \), \( d \) is the distance between the transmitter and receiver in \( Km \), \( hb \) is the transmitter antenna height in meters and \( hr \) is the receiver antenna height in meters.

### 3.3.5. Stanford University Interim (SUI Model)

The IEEE 802.16 Broadband Wireless Access Working Group introduced the Stanford University Interim (SUI) propagation model. This was derived based on the Hata model. The SUI model categorizes terrains into three types. They are terrains A, B and C. There is no specific reference to a particular environment. Terrain type A is applied for hilly environments having sizeable or very thick vegetation. This terrain type has the highest signal path loss. Terrain type B is defined for hilly regions with mild vegetation or flat terrains with moderate or lots of trees. This terrain is usually modeled for suburban environments. Terrain type C is appropriate for flat terrains. It is mostly applicable to rural environments having light vegetation. Path loss for this model is given in (16) as presented in [22]

\[
PL_{SUI} = A + 10 \log(\frac{d}{d_0}) + s \quad \text{for } f < 2GHz
\]

(16)

\[
8.2dB < s < 10.6dB
\]

\( d \) is the distance between the transmitter and receiver

\( d = 50m \)

\( f \) is the frequency in MHz

\[
A = 20\log(\frac{4}{d})
\]

(17)
\[ g(f) = 44.49 \log(f) + 4.78(\log(f))^2 + a + b + c \]

The parameters \( a, a_1, a_2, \) and \( a_3 \) given in equation (19) are constants, that can be tuned to best fit specified propagation conditions. The default values of \( a, a_1, a_2, \) and \( a_3 \) for different environment categories are specified in Table 3.

### Table 3 Default values of \( a, a_1, a_2, \) and \( a_3 \)

</tbody>
</table>

### 3.4. Path Loss Exponent

The path loss exponent which shows the lossy nature of a particular propagation environment was computed from the measurement data for each of the areas considered. [23] presents an approach to finding the path loss exponent as shown in (21).
\[
    n = \frac{\sum_{i=1}^{k} (P_{l_{do}} - P_{i}) \ast 10\log \left( \frac{d}{d_{o}} \right)}{\sum_{i=1}^{k} (10\log \left( \frac{d}{d_{o}} \right))^2}
\]

Where \( P_{i} \) is the received power at the reference distance \( d_{o} \), \( P_{l_{do}} \) is the path loss at the reference distance and \( n \) is the path loss exponent.

The expression was programmed in MATLAB for each of the measurement Environments.

### 3.5. Root Mean Square Error (RMSE)

The RMSE which measures the difference between the signal power predicted by a model and the actual measured signal was implemented in MATLAB. It served as a measure of accuracy to compare forecasting errors of the different propagation models given the drive test measurement data. It is defined mathematically by equation (22)

\[
    RMSE = \sqrt{\frac{1}{k} \sum_{k=1}^{k} \left( p_{\hat{}} - p_{i} \right)^2}
\]

Where \( p_{\hat{}} \) represents the measured power value at a specified distance, \( p_{i} \) is the predicted power value at a specified distance, \( k \) represents the number of measured samples.

To calculate the RMSE, the predicted power values for each propagation model is subtracted from the actual measured power at each environment and squared. This result is then divided by the number of measured samples, and the square root taken to arrive at the RMSE. This was implemented in MATLAB to arrive at results later discussed in section 4.

### 4. RESULTS

The results presented are two-fold. The first is at an operating frequency of 800MHz and the second at an operating frequency of 2600MHz. Results are Validated at the end of this section.

#### 4.1. Results at 800MHz

The average received power was computed for each of the measurement environments by averaging the readings taken at the three different sector antennas of the base stations. The mean received power for the different environments was compared and analyzed by plots against varying distances from the base station using MATLAB. This is shown in figure 2.

As can be observed from the graph, the Received power decreases as distance away from the Base station is increased. Deviations from this trend, however, occurred on a few occasions. This was partly as a result of obstacles and a contribution from the terrain of those environments.
4.1.1 Path Loss of Measured data

The experienced path loss at each measurement location at a distance $d(m)$ was computed as follows;

$$ P_l(dB) = EIRP(dBm) - Pr(dBm) $$  

(23)

where $Pr = \text{Mean received power in dBm}$, $EIRP = \text{Effective isotropic radiated power in dBm}$.  

$EIRP$ is given in (24) and (25)

$$ EIRP = Pt + G - L $$  

(24)

Where $G$ stands for $\text{Gains}$ and $L$ for $\text{losses}$

Typical gains considered are the antenna gains both at the transmitter and receiver end

Typical losses are connector, body and combiner loss

Expanding this yield,

$$ EIRP = Pt + G_t + G_r - L_{con} - L_{bo} $$  

(25)

$Pt = \text{Transmit power (dBm)}, G_t = \text{Gain of Transmit Antenna (dBi)}, G_r = \text{Gain of Receive antenna (dBi)}, L_{con} = \text{Connector loss (dB)}, L_{bo} = \text{Body loss (dB)}, L_{co} = \text{Combiner loss(dB)}$.

The Values of the stated parameters commonly applied in LTE Networks are given by S. A. Mawjoud [24] as:

$p_{bts} = 40W = 46dBm$, $G_{bts} = 18.15dBi$, $G_{ms} = 0dBi$, $L_{bo} = 3dB$, $L_{con} = 4.7dB$, $L_{co} = 3dB$

These parameters are substituted into equation (25)

$EIRP = 53.5dBm$

The path loss is obtained by substituting the calculated value of $EIRP$ (dBm) and the mean received power $Pr$ (dBm) into equation (23).

The effect of varying distance on Path loss for each measurement environment was investigated by plots of path loss versus distance and the graph shown below in figure 3 illustrates this.

It can be observed from the graph given in figure 3 that Path loss increases as the distance from the Base station increases. Comparing the path loss experienced for all the measurement environments, the Path loss of Adum and Afrancho is relatively higher compared to the other areas. The hilly nature of Afrancho and the presence of many high-rise buildings in Adum are good reasons to support the high path loss in these areas.
4.1.2 Comparison of Path Loss Measurement Results with Propagation Models

The path loss of each measurement environment was compared with the path loss estimations of the understudied propagation models at 800MHz for both urban (Adum and Techiman) and suburban scenarios (Agogo, Afrancho & Dorma).

Figure 4 Path Loss of Adum Compared With Path Loss of Propagation Models

Figure 5 Path Loss of Techiman Compared With Path Loss of Propagation Models

Figure 6 Path Loss of Afrancho Compared With Path Loss of Propagation Models

Figure 7 Path Loss of Agogo Compared With Path Loss of Propagation Models

Figure 8 Path Loss of New Dorma Compared With Path Loss of Propagation Models
4.1.3 Choice of Propagation Model that best fits Measurement data

Root Mean square error was used as a quantitative measure of accuracy for choosing the propagation model that best fits the measured data in the Ghanaian environment. The best propagation model was the model that had the least Root Mean squared errors (Least RMSE). The RMSE computed for the measurement areas together with the various propagation models are given in Table 4

Table 4 RMSE Values

The Ericson model had the lowest RMSE values in Urban environments as shown in Table 4. This model is therefore chosen as the model that predicts best in Urban areas in Ghana and it is further modified and improved for more accurate predictions. In the suburban environments, the SUI model had the lowest RMSE values and hence was chosen as the best model for path loss prediction in suburban cities in Ghana. It is also further modified for a more accurate prediction.

4.1.4 Modification of Ericson Model

The Ericson model which best fit measurement in the urban environments was chosen and modified to fit the measured data in urban environments. To modify and further improve the Ericson model the mean square error between the urban environments and the Ericson model was added to the standardized Ericson path loss equation.

\[ a_0 + a_1 \log(d) + a_2 \log(h_b) + a_3 \log(h_b) \log(d) - 3.2 \log(11.75h_r))^2 + g_t + \text{RMSE} \]  

RMSE for Adum =17.98

Adding the RMSE yields;

\[ a_0 + a_1 \log(d) + a_2 \log(h_b) + a_3 \log(h_b) \log(d) - 3.2 \log(11.75h_r))^2 + g_t + 17.98 \]  

This new equation with the RMSE added was plotted with measurement data from Adum together with the initial standardized Ericson model equation and the graph is shown in figure 9. It can be observed that adding the RMSE to the initial equation improves the accuracy of prediction as the modified Ericson equation fits best with the measured data.
The values of various parameters $a_0, a_1, a_2, a_3, h_p, h_r$ and $g_f$ in the Ericson model suited for an urban area were substituted into the modified equation and approximated to make the Ericson equation simple and less tedious to use yet not compromising accuracy. The resulting equation is as in equation (28)

$$P_{l_{modified}} = 68.30 + 30.2\log(d) + 0.139\log(d)$$

(28)

A similar analysis was carried out for Techiman and figure 10 shows the modified Ericson model fitting closely to measurement data from Techiman

4.1.5 Modification of SUI Model

Results of RMSE for suburban areas favored the SUI model which had the lowest RMSE values. On this basis, the SUI model was chosen as the best-fit propagation model for path loss estimation in suburban areas in Ghana. It was further modified for more accurate predictions in Ghanaian suburban environments. The RMSE each of Agogo, Afrancho and New Dorma were added to the original SUI equations and further simplified in equations (30) - (32)

$$PL_{SUI} = A + 10\gamma\log\left(\frac{d}{d_0}\right) + s \pm \text{RMSE}$$

(29)

1) modified model for Agogo

$$PL_{sui(simple)} = 72.68 + 24.54\log\left(\frac{d}{d_0}\right) + \text{RMSE}$$

(30)

2) modified model for Afrancho

$$PL_{sui(simple)} = 72.68 + 24.54\log\left(\frac{d}{d_0}\right) + \text{RMSE}$$

(31)

3) modified model for New Dorma

$$PL_{sui(simple)} = 72.6830 + 47.54\log\left(\frac{d}{d_0}\right) + \text{RMSE}$$

(32)

Graphs comparing the performance of the modified models with the original SUI models are shown in figures 11 - 13
4.2. Results at 2600MHz

The average received power was computed for each of the measurement environments by averaging the RSRP readings taken at the three different sector antennas of the base stations. The mean received power of all five measurement environments were compared against varying distance. The path loss is obtained by substituting the calculated value of EIRP (dBm) and the mean received power Pr (dBm) values also at 2600MHz into equation (29). Figure 15 compares path loss at each measurement environment with distance.

4.2.1. Path Loss of Propagation Models

Five propagation models were considered at 2600MHz. These are FSPL, SUI, COST-231, ECC-33 and Ericson model. Their path loss was calculated using parameters specified in Table 1.
4.2.2.1 Comparison of Path Loss of Measured data with Propagation models

The path loss of each measurement environment was compared with the path loss estimations of the understudied propagation models at 2600MHz for both urban(site 1, 2, 4 & 5) and suburban (site 3). Graphs are shown in Figures 16 - 20.
Observing the projected path loss of propagation models relative to measurement data in both urban and suburban environments, the ECC-33 model fits best in all cases. The Ericson and Cost 231 models predict the path loss at this frequency with a degree of error in all studied settings.

4.2.3 Path Loss Exponent at 2600MHz

The path loss exponent was computed for each measurement environment and results are given in Table 5. It is observed that the values of path loss exponents presented in Table XII agree closely with values obtained in other sub-Saharan regions. The slight variations of a few may be due to differences in factors such as building heights, town layout, street orientation and many more. This goes to explain that the environment has its effects on radio waves propagation.

4.2.4 Choice of Propagation Model that Best Fits Measurement Data at 2600MHz

Among all the propagation models considered, the ECC-33 model gave lower root mean square error values in the urban and suburban environments. Therefore, it was selected as the best model for predicting path loss in both urban and suburban environments in Ghana at 2600MHz LTE frequency. The RMSE is computed for all propagation models in Matlab and shown in Table 6.

4.2.5 Modification of ECC-33 model

Results of RMSE for both urban and suburban areas at 2600 MHz favored the ECC-33 model which had the lowest RMSE values. On this basis, this model was chosen as the best-fit propagation model for path loss estimation in urban and suburban areas in Ghana at an operating frequency of 2600MHz. A further modification was carried out on it for more accurate predictions in Ghanaian environments. The RMSE each of the five environments were added to the original ECC-33 Model equation and further simplified, resulting in equation (37)

\[ P_l = A + B - G_b - G_r \]  
\[ A = 100.6995 + 20\log(d) \]  
\[ B = 25.3321 + 9.83\log(d) \]  
\[ G_b = (\log_{10}(\frac{h_b}{200})^2 \{13.958 + 5.8(\log_{10}(d))^2\} \]  
\[ G_r = -19.7315 \]

\text{substituting } A, B \text{ & } G_r \text{ into } P_l \text{ equation yields;}

\[ P_{l_{mod}} = 145.7630 + 20\log_{10}(d) + 9.83\log_{10}(d) - G_b \pm \text{RMSE} \]

The modified Ecc-33 model for one Urban environment (Site 1) and the only suburban environment (Site 3) are plotted with the original ECC-33 model to compare their accuracy of predicting close to the measurement data. Graphs are shown in figures 21 & 22.

![Figure 21 Comparison of modified ECC-33 model and original ECC-33 model for urban environments](image1)

![Figure 22 Comparison of modified ECC-33 model and original ECC-33 model for suburban environments](image2)

The modified equations of the ECC-33 model predicts more accurately as it fits best to data from the measurement environments as can be seen in figures 23 & 24

4.2 VALIDATION

The developed models in this study were validated by calculating the error between the measured and estimated path loss for the various measurement environments using the modified equations presented. This is achieved by using equation (28) programmed in MATLAB. The values of RMSE closer to zero indicate a better fit [25],[11]. Thus, the developed models are
described as valid and suitable for the tested environments since the RMSE between the measured and the predicted path loss values are closer to zero than the initial RMSE values. Tables 7 & 18 show the RMSE generated using the developed models in this thesis at 800MHz and 2600MHz respectively.

The improved models developed were further compared with the path loss simulated by the use of the NYUSIM simulator. This is a simulation tool developed by the New York University (NYU) wireless team and relies on huge amounts of true measured data at mm-wave frequencies in New York[27]. The simulator incorporates the CI propagation model [28]. Developed models show consistent prediction behavior compared with the NYU simulator’s path loss and hence can be considered valid models for use in the Ghanaian environment with similar environmental features as the measurement environments.

5. CONCLUSION

This study was focused on developing improved versions of industry-standard propagation models suited for LTE path loss prediction in the Ghanaian environment. Path loss of four propagation models was compared with Path loss of propagation measurements taken from five LTE 800MHz base stations located in the urban and suburban areas of Ghana using MATLAB. Results confirmed the initial assumption of the study, that propagation models predict far from the ideal. The Ericson model showed satisfactory performance in the urban environments at 800MHz. This model however over predicted the path loss in the suburban environments. The SUI model outperformed the other models in predicting close to the propagation measurement in suburban areas at 800MHz. The Ericson and SUI models were further improved for a more accurate prediction of LTE path loss in urban and suburban Ghanaian environments at 800MHz.

For similar studies at an LTE frequency of 2600MHz, the Path loss of five propagation models was compared with the Path loss of propagation measurements taken at five base stations located in the urban and suburban areas of Ghana. The ECC-33 model best fit propagation measurements both in the urban and suburban environments and hence it was developed further for use in LTE path loss estimation at 2600MHz.

From the results presented, measurement data ascertained the fact that propagation models predict far from the ideal. The modified equations presented in this paper can be used in Ghanaian settings having similar characteristics with the Areas considered in this paper by network operators for accurate and simplified path loss prediction.
